1.

a.

A random variables series is covariance constant, so if all sequential terms have the same average, and if the series covariance only depends on the relative locations of the two terms, i.e., on how much they are a part, and not just on their actual location, that is, in which the sequence is placed (Sharma, 2012).

b.

The autocovariance function may be interpreted as calculating the memory or the identification of the signal deviation by its mean point. The cross-covariance method, therefore offers a test of the correlation of the two signals' divergence from their mean values.

distinct parts of the series have an asymptotic covariance decreasing to 0. In various probabilistic limit theorems, low dependence primarily occurs as a technological condition. The weak dependency of several normal instances of stochastic processes is a necessary weak state. Poor dependency, in particular, is a common condition for the random function theory (Illowsky & Dean, 2017).

d.

regression equation for the next stage to determine the output. It is a very basic concept that can lead to a variety of time series problems with specific predictions (Sharma, 2012).

2.

Both year and county parameters measure the differential effect of the new policy on divorce rates in Ohio, compared to Pennsylvania. The new policy is introduced after the new policy introduction.

econometrics and biostatistics, to a regression model where the group meaning is constant (non-random) instead of a random impact model, in which the group means is a representative sample from a population (Rakshit, 2018).

If a survey depletes the samples, the associated variable is defined. The subsequent
